ANATATSION

The article analyzes the role of microcracks in fractures and evaluates the strength of solids in the framework of continuum mechanics concepts. It is shown that although the assessment of the role of microcracks in the fracture and strength of solids proposed by Griffiths was an important step, this approach does not take into account the dynamic role of the occurrence of microcracks and the relaxation nature of the absorption of the released elastic deformation energy. The involvement of the concepts and achievements of micromechanics of destruction in teaching the relevant topics of the course of physics makes it possible to acquaint pupils and students with the real problems of modern science and thereby increase the efficiency of the educational process.

Keywords: theoretical and real strength, microcrack, elastic deformation energy, absorption energy, teaching physics.

The properties of resisting a solid to an external load are called strength. Strength is the most important physical and mechanical characteristic of solids. Despite the enormous achievements of crystal physics, the strength of crystalline bodies is still determined experimentally by laboratory methods.

The calculation of the strength of crystals by means of the interaction potential of atoms (theoretical strength), which was made by a number of scientists, showed that it significantly (100 - 1000 times!) exceeds the real strength. It was necessary to find out the reason for this discrepancy.

Griffiths, an English scientist, attributed the reason for the decrease in real strength to the presence of microscopic cracks that are present in almost all real solids. It is clear that at the tip of the microcrack, the mechanical stress is significantly greater than the average. Academician A.F.Ioffe in experiments with salt crystals showed that when etching the crystal surface (with water), the strength of the crystal increases 5-7 times. S.N.Zhurkov and A.P. Alexandrov in the experiment showed that, as the diameter of the glass threads decreases, their strength increases sharply.

Thus, the calculation of the theoretical strength and its strong difference from the real strength became the reason for scientific research in order to find out the reason for such a discrepancy and to find ways to increase the strength of solids. Since ―the margin‖ up to the theoretical strength was quite a lot. These studies in physics and technology of solids have yielded two important results. Firstly, various methods have been developed for obtaining filamentous crystals, the strength of which is close to theoretical. Secondly, a new theory on the strength of solids has been developed, the thermofluctuational (kinetic) theory of the destruction of solids.
Nevertheless, the kinetic theory does not deny the role of microcracks in the process of destruction of solids. On the contrary, in the Zhurkov-Regel scientific school, the occurrence of submicrocracks in a loaded body is considered as a consequence of thermal fluctuation.
Professor Lexovsky and his students, based on an in-depth study of the origin and development of microcracks in polymers and polycrystalline metals in an electron microscope chamber, showed that, firstly, microcracks appear explosively, and secondly, their interactions have a relaxation nature almost until the end of the sample's life.
In a direct experiment using an electron microscope and statistical analysis of acoustic signals that occur during deformation of a fibrous composite, it is shown that: the transition from the accumulation of dispersed defects (microcracks) to catastrophic (uncontrolled) destruction occurs there and when the released elastic deformation energy (when a defect occurs) cannot be absorbed by the surrounding volume. Such a state occurs as deformation occurs, when all channels of energy dissipation of elastic deformation are exhausted.
That is, the ratio of the elastic deformation energy, which is released in a unit of time during the explosive appearance of microscopic defects in a loaded body, and the ability of a solid body to absorb this energy determines the future fate of the loaded body. If the loaded solid is still able to absorb the released elastic deformation energies, then the body can maintain its integrity. However, if the elastic deformation energy released in a unit of time cannot be absorbed by the surrounding volume, then the body collapses – the destruction becomes catastrophic.
Due to the importance of the task of predicting the transition from dispersed destruction to catastrophic, the article (report) provides detailed information on the calculation of real strength and the role of microcracks in the process of destruction of solids.
Consider Griffiths' approach. Suppose a tensile stress σ is applied to a thin plate of a brittle solid (Fig. 1). According to the law of conservation of energy, the work of external forces during deformation accumulates in the volume of the body in the form of elastic deformation energy. Let's try to calculate the elastic deformation energies.
When deformed by Δl in a sample with a cross section S and an elastic modulus E, an external force does the work:

$A = \overline{F\Delta l}$ (1)

Where here is the average strength. It is clear that at the beginning of the deformation F=0 . When deformed by Δl the external force will reach the maximum value of the modulus, which is equal to the elastic force $F_{max} = F_ч$. Therefore, the average force is $\overline{F} = \frac{1}{2}F_m$ (2) .

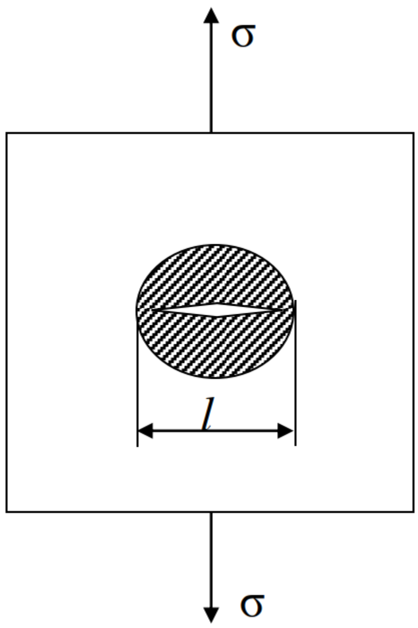

Рис. 1

Taking into account (2) we get: $A = \overline{F}\Delta l = \frac{1}{2}F\Delta l$ (3).

On the other hand: $F = \sigma \cdot S$ (4) .

Putting expression (4) on (3) we get the following:

$A = \frac{1}{2}\sigma \cdot S\Delta l$ (5)

It is known that $\varepsilon = \frac{\Delta l}{l}$ from here: $\Delta l = \varepsilon \cdot l$ (6) the value of Δl (expression (6) is put on (5) and we get:

$A = W = \frac{1}{2}\sigma \cdot S \cdot \Delta l = \frac{1}{2}\sigma \cdot S \cdot \varepsilon \cdot l = \frac{1}{2}\sigma \cdot \varepsilon \cdot V$ (7)

From Hooke's Law $\varepsilon = \frac{\sigma}{E}$ (8)

We set the value from (8) to (7) and get the elastic deformation energy formulas:

$W = \frac{1}{2}\sigma \cdot \frac{\sigma}{E} \cdot V = \frac{\sigma^2}{2E} \cdot V$ (9)

Hence the energy density of elastic deformation (ω):

$\omega = \frac{W}{V} = \frac{\sigma^2}{2E}$ (10)

Suppose, under the influence of external mechanical stress, a microcrack of length l occurs in the sample, which covers the entire thickness of the sample δ. As a result of the occurrence of a crack inside the sample ,свободный поверхность $S \approx 2l \cdot \delta$

This leads to an increase in the energy of the sample by $\Delta W_1 = 2l \cdot \delta \cdot \alpha$ (11) . Where here α is the energy of the free surface.On the other hand, as a result of the occurrence of a crack, the volume of the sample $V = l^2 \cdot \delta$ it is released from mechanical stress. As a result, the elastic deformation energy of the sample decreases in the amount of $\Delta W_2 = l^2\delta \cdot \sigma^2/(2E)$ (12)

The change in the energy of the sample ΔW as a result of the formation of a crack:

$\Delta W = 2l \cdot \delta \cdot \alpha - l^2\delta \cdot \frac{\sigma^2}{2E}$ (13)

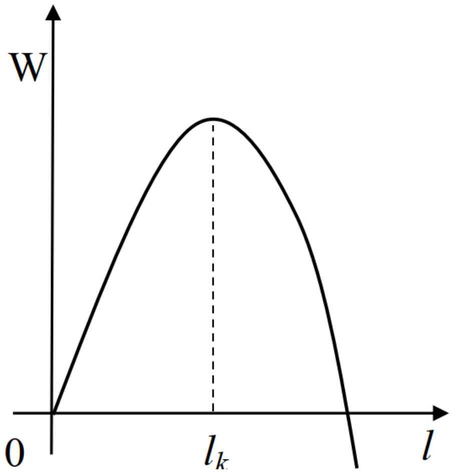
Figure 2 shows the dependence of the energy on the crack length. This dependence has a maximum where the energy derivative of the length is zero.

$\frac{dW}{dl} = 2\delta \cdot \alpha - l \cdot \delta \cdot \frac{\sigma^2}{E} = 0$ (14)

The length of the crack corresponding to the maximum is denoted by l_k . From the last expression we get: $l = 2\alpha \cdot E/\sigma^2$ (15)

Setting the values of the quantities α, E и σ for copper crystal ($\alpha \approx \frac{1{,}7Дж}{м^2}; E = 1{,}2 \cdot 10^{11}Па$ и $\sigma_р = 1{,}8 \cdot 10^8Па$) in formula (15) we get: $l \approx 10 \cdot 10^{-6}м$ [11].

Consequently, when a microcrack of ~ 10 microns occurs, the destruction becomes irreversible.



From Fig.2 at l≤l_k, an increase in the crack length leads to an increase in energy. At l≥l_k, as the crack length increases, the energy of the sample decreases (the principle of minimum energy). This leads to a spontaneous increase in the crack, which leads to catastrophic destruction. Using (15), Griffiths obtained an expression for calculating the real strength of solids, assuming that solids almost always have microcracks: $\sigma_{нь} = (2\alpha E/l)^{1/2}$ (16)

Although Griffiths' theory was a serious step to explain the difference between the theoretical and real strength of solids, however, this theory does not take into account the role of thermal motion of atoms and the dynamic nature of the occurrence of microcracks in loaded bodies. Indeed, the elastic deformation energy that is released during the explosive occurrence of microcracks in a loaded body is an important factor that can significantly affect the development of the fracture process.

For filamentous crystals and glass fibers with high strength, the appearance of a single accidental microcrack leads to macro-destruction of the sample. In the case of plastic materials, this transition occurs rather slowly. The creation of an adequate theory predicting the transition from dispersed micro-fractures to catastrophic destruction requires taking into account not only the size of microcracks appearing in the volume of the loaded body, but also the power ratio of the released elastic deformation energy and energy absorption of the material. The use of the concepts of micromechanics of destruction in teaching the relevant topics of the physics course allows students to familiarize students with the real problems of solid state physics and thereby increase the efficiency of the educational process.
